

| Activity No. 4.2 Strings | |
|---|--------------------------------------|
| Course Code: CPE 103 | Program: Computer Engineering |
| Course Title: Object Oriented Programming | Date Performed: 04/12/2025 |
| Section: 1-A | Date Submitted: 04/12/2025 |
| Name: GABIJAN, RHOVIC M. | Instructor: ENGR. SAYO |
| 1. Objective(s) | |
| This activity aims to demonstrate the students' understanding of strings implementation in solving problems. | |
| 2. Intended Learning Outcomes (ILOs) | |
| After this module, the students should be: <ul style="list-style-type: none"> Demonstrate the implementation of strings in different use cases and acquire skills in solving difficult problems using strings. | |
| 3. Discussion | |
| <p>A string is a sequence</p> <p>A string is a <i>sequence</i> of characters. You can access the characters one at a time with the bracket operator:</p> <pre>>>> fruit = 'banana' >>> letter = fruit[1]</pre> <p>The second statement extracts the character at index position 1 from the fruit variable and assigns it to the letter variable.</p> <p>The expression in brackets is called an <i>index</i>. The index indicates which character in the sequence you want (hence the name).</p> <p>But you might not get what you expect:</p> <pre>>>> print(letter)</pre> <p>a</p> <p>For most people, the first letter of “banana” is “b”, not “a”. But in Python, the index is an offset from the beginning of the string, and the offset of the first letter is zero.</p> <pre>>>> letter = fruit[0] >>> print(letter)</pre> <p>b</p> <p>So “b” is the 0th letter (“zero-th”) of “banana”, “a” is the 1th letter (“one-th”), and “n” is the 2th (“two-th”) letter.</p> <p>String Indexes</p> <p>You can use any expression, including variables and operators, as an index, but the value of the index has to be an integer. Otherwise you get:</p> <pre>>>> letter = fruit[1.5]</pre> <p>TypeError: string indices must be integers</p> <p>Getting the length of a string using len</p> <p>len is a built-in function that returns the number of characters in a string:</p> <pre>>>> fruit = 'banana' >>> len(fruit)</pre> <p>6</p> <p>To get the last letter of a string, you might be tempted to try something like this:</p> <pre>>>> length = len(fruit)</pre> | |

```
>>> last = fruit[length]
```

IndexError: string index out of range

The reason for the IndexError is that there is no letter in “banana” with the index 6. Since we started counting at zero, the six letters are numbered 0 to 5. To get the last character, you have to subtract 1 from length:

```
>>> last = fruit[length-1]
```

```
>>> print(last)
```

a

Alternatively, you can use negative indices, which count backward from the end of the string. The expression `fruit[-1]` yields the last letter, `fruit[-2]` yields the second to last, and so on.

Traversal through a string with a loop

A lot of computations involve processing a string one character at a time. Often they start at the beginning, select each character in turn, do something to it, and continue until the end. This pattern of processing is called a *traversal*. One way to write a traversal is with a while loop:

```
index = 0
```

```
while index < len(fruit):
```

```
    letter = fruit[index]
```

```
    print(letter)
```

```
    index = index + 1
```

This loop traverses the string and displays each letter on a line by itself. The loop condition is `index < len(fruit)`, so when `index` is equal to the length of the string, the condition is false, and the body of the loop is not executed. The last character accessed is the one with the index `len(fruit)-1`, which is the last character in the string.

Another way to write a traversal is with a for loop:

```
for char in fruit:
```

```
    print(char)
```

Each time through the loop, the next character in the string is assigned to the variable `char`. The loop continues until no characters are left.

String slices

A segment of a string is called a *slice*. Selecting a slice is similar to selecting a character:

```
>>> s = 'Monty Python'
```

```
>>> print(s[0:5])
```

Monty

```
>>> print(s[6:12])
```

Python

The operator `[n:m]` returns the part of the string from the “n-th” character to the “m-th” character, including the first but excluding the last.

If you omit the first index (before the colon), the slice starts at the beginning of the string. If you omit the second index, the slice goes to the end of the string:

```
>>> fruit = 'banana'
```

```
>>> fruit[:3]
```

'ban'

```
>>> fruit[3:]
```

'ana'

If the first index is greater than or equal to the second the result is an *empty string*, represented by two quotation marks:

```
>>> fruit = 'banana'
>>> fruit[3:3]
''
```

An empty string contains no characters and has length 0, but other than that, it is the same as any other string.

Strings are immutable

It is tempting to use the operator on the left side of an assignment, with the intention of changing a character in a string. For example:

```
>>> greeting = 'Hello, world!'
>>> greeting[0] = 'J'
```

TypeError: 'str' object does not support item assignment

The “object” in this case is the string and the “item” is the character you tried to assign. For now, an *object* is the same thing as a value, but we will refine that definition later. An *item* is one of the values in a sequence.

The reason for the error is that strings are *immutable*, which means you can't change an existing string.

The best you can do is create a new string that is a variation on the original:

```
>>> greeting = 'Hello, world!'
>>> new_greeting = 'J' + greeting[1:]
>>> print(new_greeting)
```

Jello, world!

This example concatenates a new first letter onto a slice of greeting. It has no effect on the original string.

Looping and counting

The following program counts the number of times the letter “a” appears in a string:

```
word = 'banana'
count = 0
for letter in word:
    if letter == 'a':
        count = count + 1
print(count)
```

This program demonstrates another pattern of computation called a *counter*. The variable count is initialized to 0 and then incremented each time an “a” is found. When the loop exits, count contains the result: the total number of a's.

The in operator

The word in is a boolean operator that takes two strings and returns True if the first appears as a substring in the second:

```
>>> 'a' in 'banana'
True
>>> 'seed' in 'banana'
False
```

String comparison

The comparison operators work on strings. To see if two strings are equal:

```
if word == 'banana':
```

```
    print('All right, bananas.')
```

Other comparison operations are useful for putting words in alphabetical order:

```
if word < 'banana':
```

```
    print('Your word,' + word + ', comes before banana.')
```

```
elif word > 'banana':
```

```
    print('Your word,' + word + ', comes after banana.')
```

```
else:
```

```
    print('All right, bananas.')
```

Python does not handle uppercase and lowercase letters the same way that people do. All the uppercase letters come before all the lowercase letters, so:

Your word, Pineapple, comes before banana.

A common way to address this problem is to convert strings to a standard format, such as all lowercase, before performing the comparison. Keep that in mind in case you have to defend yourself against a man armed with a Pineapple.

String methods

Strings are an example of Python *objects*. An object contains both data (the actual string itself) and *methods*, which are effectively functions that are built into the object and are available to any *instance* of the object.

Python has a function called `dir` which lists the methods available for an object. The `type` function shows the type of an object and the `dir` function shows the available methods.

```
>>> stuff = 'Hello world'
```

```
>>> type(stuff)
```

```
<class 'str'>
```

```
>>> dir(stuff)
```

```
[... 'capitalize', 'casefold', 'center', 'count', 'encode',  
'endswith', 'expandtabs', 'find', 'format', 'format_map',  
'index', 'isalnum', 'isalpha', 'isdecimal', 'isdigit',  
'isidentifier', 'islower', 'isnumeric', 'isprintable',  
'isspace', 'istitle', 'isupper', 'join', 'ljust', 'lower',  
'lstrip', 'maketrans', 'partition', 'replace', 'rfind',  
'rindex', 'rjust', 'rpartition', 'rsplit', 'rstrip',  
'split', 'splitlines', 'startswith', 'strip', 'swapcase',  
'title', 'translate', 'upper', 'zfill']
```

```
>>> help(str.capitalize)
```

Help on method_descriptor:

```
capitalize(self, /)
```

Return a capitalized version of the string.

More specifically, make the first character have upper case and the rest lower case.

```
>>>
```

While the `dir` function lists the methods, and you can use `help` to get some simple documentation on a method.

Calling a *method* is similar to calling a function (it takes arguments and returns a value) but the syntax is different. We call a method by appending the method name to the variable name using the period as a delimiter.

For example, the method `upper` takes a string and returns a new string with all uppercase letters: Instead of the function syntax `upper(word)`, it uses the method syntax `word.upper()`.

```
>>> word = 'banana'
>>> new_word = word.upper()
>>> print(new_word)
BANANA
```

This form of dot notation specifies the name of the method, `upper`, and the name of the string to apply the method to, `word`. The empty parentheses indicate that this method takes no argument.

A method call is called an *invocation*; in this case, we would say that we are invoking `upper` on the word. For example, there is a string method named `find` that searches for the position of one string within another:

```
>>> word = 'banana'
>>> index = word.find('a')
>>> print(index)
1
```

In this example, we invoke `find` on `word` and pass the letter we are looking for as a parameter.

The `find` method can find substrings as well as characters:

```
>>> word.find('na')
2
```

It can take as a second argument the index where it should start:

```
>>> word.find('na', 3)
4
```

One common task is to remove white space (spaces, tabs, or newlines) from the beginning and end of a string using the `strip` method:

```
>>> line = ' Here we go '
>>> line.strip()
'Here we go'
```

Some methods such as *startswith* return boolean values.

```
>>> line = 'Have a nice day'
>>> line.startswith('Have')
```

```
True
>>> line.startswith('h')
```

```
False
```

You will note that `startswith` requires case to match, so sometimes we take a line and map it all to lowercase before we do any checking using the `lower` method.

```
>>> line = 'Have a nice day'
>>> line.startswith('h')
```

```
False
>>> line.lower()
'have a nice day'
```

```
>>> line.lower().startswith('h')
```

```
True
```

In the last example, the method `lower` is called and then we use `startswith` to see if the resulting lowercase string starts with the letter “h”. As long as we are careful with the order, we can make multiple method calls in a single expression.

Parsing strings

Often, we want to look into a string and find a substring. For example if we were presented a series of lines formatted as follows:

```
From stephen.marquard@uct.ac.za Sat Jan 5 09:14:16 2008
```

and we wanted to pull out only the second half of the address (i.e., `uct.ac.za`) from each line, we can do this by using the `find` method and string slicing.

First, we will find the position of the at-sign in the string. Then we will find the position of the first space *after* the at-sign. And then we will use string slicing to extract the portion of the string which we are looking for.

```
>>> data = 'From stephen.marquard@uct.ac.za Sat Jan 5 09:14:16 2008'
```

```
>>> atpos = data.find('@')
```

```
>>> print(atpos)
```

```
21
```

```
>>> spos = data.find(' ', atpos)
```

```
>>> print(spos)
```

```
31
```

```
>>> host = data[atpos+1:spos]
```

```
>>> print(host)
```

```
uct.ac.za
```

```
>>>
```

We use a version of the `find` method which allows us to specify a position in the string where we want find to start looking. When we slice, we extract the characters from “one beyond the at-sign through up to *but not including* the space character”.

Formatted String Literals

A formatted string literal (often referred to simply as an f-string) allows Python expressions to be used within string literals. This is accomplished by prepending an `f` to the string literal and enclosing expressions in curly braces `{}`.

For example, wrapping a variable name in curly braces inside an f-string will cause it to be replaced by its value:

```
>>> camels = 42
```

```
>>> f'{camels}'
```

```
'42'
```

The result is the string `'42'`, which is not to be confused with the integer value `42`.

An expression can appear anywhere in the string, so you can embed a value in a sentence:

```
>>> camels = 42
```

```
>>> f'I have spotted {camels} camels.'
```

```
'I have spotted 42 camels.'
```

Several expressions can be included within a single string literal in order to create more complex strings.

```
>>> years = 3
```

```
>>> count = .1
>>> species = 'camels'
>>> f'In {years} years I have spotted {count} {species}.'
'In 3 years I have spotted 0.1 camels.'
```

PY4E - Python for everybody. (n.d.). <https://www.py4e.com/html3/06-strings>

4. Materials and Equipment

To properly perform this activity, the student must have:

- Python
- Spyder IDE
- Jupyter Notebook

5. Procedure

1. Open the Anaconda.
2. Use the jupyter notebook and follow the instructions below.
3. Provide a screenshot for every test case in each code and insert in the Output section with a corresponding description and observation.

A string is a sequence

```
[ ] fruit = 'banana'
    letter = fruit[1]
```

```
[ ] print(letter)
```

```
[ ] letter = fruit[0]
    print(letter)
```

```
[ ] letter = fruit[1.5]
```

Getting the length of a string using len

```
[ ] fruit = 'banana'  
    len(fruit)
```

```
[ ] length = len(fruit)  
    last = fruit[length]
```

```
[ ] last = fruit[length-1]  
    print(last)
```

Traversal through a string with a loop

```
[ ] index = 0  
    while index < len(fruit):  
        letter = fruit[index]  
        print(letter)  
        index = index + 1
```

```
[ ] for char in fruit:  
    print(char)
```

String slices

```
[ ] s = 'Monty Python'  
    print(s[0:5])
```

```
[ ] print(s[6:12])
```

```
[ ] fruit = 'banana'  
    fruit[:3]
```

```
[ ] fruit[3:]
```

```
[ ] fruit = 'banana'  
    fruit[3:3]
```

Strings are immutable

```
[ ] greeting = 'Hello, world!'
    greeting[0] = 'J'
```

```
[ ] greeting = 'Hello, world!'
    new_greeting = 'J' + greeting[1:]
    print(new_greeting)
```

Looping and counting

```
[ ] word = 'banana'
    count = 0
    for letter in word:
        if letter == 'a':
            count = count + 1
    print(count)
```

6. Output

Provide an output of your work here. (include an analyzation for every screenshot or output)

A STRING IS A SEQUENCE

```
[7] fruit = 'banana'
    letter = fruit[1]

    print(letter)
```

⇒ a

Since positive index is start in 0 that's why the 'a' will become index 1.

```
fruit = 'banana'
letter = fruit[0]

print(letter)

b
```

Positive index always starts in 0 so if we write the codes `fruit[0]` it will find the 0 index which is the 'b'.

```
fruit = 'banana'
letter = fruit[1.5]

print(letter)

-----
TypeError                                 Traceback (most recent call last)
<ipython-input-70-ee002b43b3b4> in <cell line: 0>()
      1 fruit = 'banana'
----> 2 letter = fruit[1.5]
      3
      4 print(letter)

TypeError: string indices must be integers, not 'float'
```

Indexing does not support decimal so 1.5 does not exist in the program and will make it error.

GETTING THE LENGTH OF A STRING USING LEN

```
fruit = 'banana'
len(fruit)

6
```

If we are finding the len we have to start in 1 just like counting how many letters in 'banana'.

```
fruit = 'banana'
length = len(fruit)
last = fruit[length]

-----
IndexError                                 Traceback (most recent call last)
<ipython-input-71-05ab9570bc40> in <cell line: 0>()
      1 fruit = 'banana'
      2 length = len(fruit)
----> 3 last = fruit[length]

IndexError: string index out of range
```

The error of this code is the length since len is counting from 1-6, this is not existed in length because the index are from 0-5

```
fruit = 'banana'
length = len(fruit)
last = fruit[length-1]

print(last)

a
```

To avoid error in code we must subtract it by 1 so that it will become 0 to 5

TRANVERSAL THROUGH A STRING WITH A LOOP

```
index = 0
while index < len(fruit):
    letter = fruit[index]
    print(letter)
    index = index + 1

b
a
n
a
n
a
```

While loop is continual it continues until it satisfies its condition, that's why we use < and increment the index to avoid infinite 'banana' word.

```
index = 0
for char in fruit:
    print(char)

b
a
n
a
n
a
```

In for loop is only limited in the assigned condition.

STRING SLICES

```
s = 'Monty Python'
print(s[0:5])

print(s[6:12])

Monty
Python
```

String slicing is done with s[start:end], and the end index is not included so it print Monty while the second word is Python

```
fruit = 'banana'
fruit[:3]

fruit[3:]

'ana'
```

[:3] start from the beginning and end with index 2, while [3:] start from index 3 to the end.

```
fruit = 'banana'
fruit[3:3]

..
```

Since it start with index 3 and end 3 it doesn't include anything

STRINGS ARE IMMUTABLE

```
greeting = 'Hello World!'
greeting[0] = 'J'
```

```
-----
TypeError                                Traceback (most recent call last)
<ipython-input-76-ed50419eeaf9> in <cell line: 0>()
      1 greeting = 'Hello World!'
----> 2 greeting[0] = 'J'

TypeError: 'str' object does not support item assignment
```

It was error since Strings are immutable.

```
greeting = 'Hello World!'
new_greeting = 'J' + greeting[1:]
print(new_greeting)
```

```
Jello World!
```

Since strings are immutable you must replace the first character of 'Hello World!' with J. this is the correct way to modify the code.

LOOPING AND COUNTING

```
word = 'banana'
count = 0
for letter in word:
    if letter == 'a':
        count = count + 1
print(count)
```

```
3
```

The code counts how many time letter "a" appears in the word 'banana' and print the result.

7. Supplementary Activity

Solve the following problems:

1. Take the following Python code that stores a string:

```
str = 'CPE-CPE009A-2025: 0.8475'
```

Use find and string slicing to extract the portion of the string after the colon character and then use the float function to convert the extracted string into a floating point number.

*Insert the code and the output here with the corresponding analyzation.

```
str = 'CPE-CPE009A-2025: 0.8475'

index = str.find(':')

number = str[index+1:].strip()
x = float(number)
print(x)

0.8475
```

The code extracts the number after the colon using find and strip

2. Write a python program that asks the user for their first name and convert it in to as a string. Print out the 3 words middle of the name using slice.

*Insert the code and the output here with the corresponding analyzation.

```
fname = (input("Enter First name: "))

if len(fname)<3:
    print("Name must be atleast 3 characters.")
else:
    midname = len(fname)//2
    midthree = fname[midname-1:midname+2]

    print("The middle 3 letters are:", midthree)

Enter First name: Rhovic
The middle 3 letters are: ovi
```

This codes extracts and print 3 character in the middle using the len.

8. Conclusions/Observations

In conclusion, string is a sequence that are immutable, meaning it cannot change directly from the string. We can also find the length of a string using a len method, as well as looping. String slicing is use to extract are partial characters from the string.

9. Assessment Rubric
